Received September 20, 1983

Various multivariate stochastic process models have been developed to represent human physiological aging and mortality. These efforts are extended by considering the effects of observed and unobserved state variables on the age trajectory of physiological parameters. This is done by deriving the Kolmogorov–Fokker–Planck equations describing the distribution of the unobserved state variables conditional on the history of the observed state variables. Given some assumptions, it is proved that the distribution is Gaussian. Strategies for estimating the parameters of the distribution are suggested based on an extension of the theory of Kalman filters to include systematic mortality selection. Various empirical applications of the model to studies of human aging and mortality as well as to other types of “failure” processes in heterogeneous populations are discussed. © 1985 Academic Press, Inc.

I. INTRODUCTION

A number of models of human aging and mortality have been developed which attempt to describe the physiological mechanisms underlying age correlated changes in health and the risk of morbidity and mortality (see
The essential components of such models are stochastic differential equations which describe the time-directed process by which individuals change position in a multivariate state space defined by physiological variables. For example, Sacher and Trucco (1962) produced a model that described physiological aging as a process which maintained homeostasis in a multivariate state space and mortality as an exceedance of a threshold value on some physiological variable beyond which the homeostatic forces were no longer effective.

A recent alternative formulation has been presented by Woodbury and Manton (1977, 1983). The principle feature of this model is that human aging and mortality is described by two distinct processes. The first type of process is a random walk for the individual where the individual's future profile of physiological values (i.e., his future physiological "state") is a result of both a deterministic function of his current "state" and a stochastic term. The second type of process describes the risk of "mortality" as a probabilistic function of his current state. At the population level, Woodbury and Manton describe the change in the multivariate distribution of the state variables by a Kolmogorov–Fokker–Planck (KFP) equation. In the KFP equation, they specify four types of physiological dynamics: drift (i.e., systematic change in mean values), regression (i.e., convergence to mean values, due perhaps to homeostatic tendencies), diffusion (i.e., divergence due to random influences), and mortality selection (i.e., loss from the population of frail individuals). To apply the KFP equation they assume that the process is Markovian. The model has been applied to both epidemiological studies of chronic disease risk (Woodbury et al., 1979) and to longitudinal studies of normal aging processes (Woodbury and Manton, 1983; Manton and Woodbury, 1983).

In this paper we generalize Woodbury and Manton's model to deal with non-Markovian processes, measurement error, and the combination of observed and unobserved variables. We present our results in a way designed to show how additional information about the state variables influences an observer's understanding of the temporal change of the physiological system.

Our model is based on the assumption that each individual is characterized by a set of variables that change over time. Some of these variables are measured; the rest are not observed over time, but some information is available about them. Specifically, we assume knowledge of the probability distribution of the unobserved variables at the initial time zero as well as of the stochastic differential equations describing their random time path. The stochasticity in the aging process is generated by a Wiener (i.e., Brownian motion) process, as well as by the randomness in the initial values of unobserved variables. The force of mortality is a function of an individual's position in the state space.

We deal with the observed variables by developing a form of the KFP
equation that describes the change in the distribution of the unobserved variables conditional both on survival to age $t$ and on the trajectories of the observed variables. We then show that if the force of mortality for an individual is a quadratic function of the unobserved variables, it is possible to estimate the means and variances of the unobserved variables over time. The equations used are similar to the Kalman filter equations developed by communication theorists to estimate signals. The equations, however, generalize the usual Kalman filter equations to include systematic mortality.

The force of mortality as a function of age and observed life history can be directly estimated. As noted above, however, estimates based directly on the observed data pertain only to the surviving population and not to the population as a whole or to any homogeneous subgroup within it. The surviving population differs from the entire population because of systematic mortality selection. Specifically, individuals at high mortality risk on the unobserved variables will die off more rapidly and thus will be underrepresented in the surviving population. We show that, given the estimates of the means and variances of the unobserved variables, it is possible to calculate the force of mortality for individuals at age $t$ with identical observed as well as unobserved characteristics. Thus, the impact on aging and mortality of each of the observed and unobserved variables can be identified.

The remainder of our presentation is organized as follows:

(1) We describe three different formulations of a model of aging and mortality based on Woodbury and Manton's suggestions. The first formulation describes the process for a single unobserved variable using a simple version of the Woodbury-Manton model. The second formulation shows how the basic process is modified to include observations of time of death. The third formulation introduces a second state variable which is continuously monitored over time. For these three cases, we derive the equations, based on the KFP equation, that give the (conditional) density of the unobserved variable. We discuss how the various increments in information affect the description of the dynamics of the aging and mortality process. In a fourth section of this part of the paper, we sketch two extensions of the model: we allow the stochastic differential equations that describe the trajectories of the variable to depend on the entire history of the observed variable, and we indicate how the model can be generalized to an arbitrary number of observed and unobserved variables.

(2) We briefly review the restrictions and assumptions suggested by Woodbury and Manton to estimate the distribution of the unobserved variables. We make some analogous restrictions and assumptions and prove some results concerning the Gaussian form of the distribution. By extending the theory of Kalman filters, we present equations for the mean and variance
of this distribution. In addition, we give the equation for calculating the force of mortality of individuals at time $t$ with any specified set of observed and unobserved characteristics.

(3) We discuss applications of the model to empirical studies of aging and mortality processes with observed and unobserved variables.

(4) We conclude with a discussion of how our model of human aging and mortality relates to other attempts to study the general problem of determining the effects on a stochastic process of systematic population loss due to mortality or other discrete state transitions.

II. ALTERNATIVE FORMULATIONS OF A MODEL OF AGING AND MORTALITY

A. The Basic Model

In this section we describe a model of aging and mortality of the general type suggested by Woodbury and Manton (1977). To facilitate comparisons, we describe this model in terms of a single physiological or environmental variable $Y(t)$: generalization to an arbitrary number of variables is in principle straightforward. In addition to the process describing changes in physiological states we will represent time of death by a nonnegative random variable $T$ whose distribution depends on the path of $Y(t)$ over the interval $(0, t)$, denoted $Y_0$. Hence, in addition to the evolution of $Y(t)$ described by a stochastic differential equation, the model includes an additional random process that is described by a mortality indicator $I(t)$, where

$$I(t) = 1 \text{ if } T > t, \text{ otherwise } I(t) = 0. \quad (1)$$

The complete time path of each individual is thus described by $Y_0 T$. This path is assumed to result from a random process in which the change in any value $Y(t)$ is described by

$$dY(t) = a(t, Y(t)) \, dt + b(t, Y(t)) \, dW(t). \quad (2)$$

In (2), $W$ is a Wiener process that is independent of the initial value $Y(0)$, which is a random variable whose distribution is known. In addition it is assumed that the coefficients $a$ and $b$ are known (e.g., estimated from an alternative data source or specified from theory). Though we have information on the temporal change of the distribution function we assume that we do not have information on the physiological state or mortality status of individuals, i.e., the individual values $Y(t)$ and $I(t)$ are not known. The conditional distribution of $T$ is given by

$$P(T > t \mid Y_0) = e^{-\int_0^t a(s, Y(s)) \, ds}, \quad (3)$$
where \( \mu \) is a bounded function, assumed known, that can be interpreted as the force of mortality for individuals at time \( t \) with a specific value of \( Y(t) \), and where \( Y_0 \) represents the entire history of \( Y \) from time 0 to time \( t \).

Let us define the joint density function of \( Y(t) \) and probability of event \( (T > t) \) as follows:

\[
f_t(y) = \frac{\partial}{\partial y} P(Y(t) \leq y, T > t) = \frac{\partial}{\partial y} P(Y(t) \leq y, I(t) = 1).
\]  

As Woodbury and Manton note, the change in this density function over time is governed by the Kolmogorov–Fokker–Planck equation:

\[
\frac{\partial f_t(y)}{\partial t} = -\frac{\partial}{\partial y} [a(t, y)f_t(y)] + \frac{1}{2} \frac{\partial^2}{\partial y^2} [b^2(t, y)f_t(y)] - \mu(t, y)f_t(y).
\]  

The three additive terms in this equation reflect the different forces affecting the dynamics of change in the distribution of \( Y(t) \). The first term describes the effects usually called drift and regression; the second term, the effects of diffusion; and the third term, the effects of mortality selection.

B. The Model When Death is Observed

Suppose now that the time of individuals' deaths are observed, so that it is known whether \( T \), the time of death for an individual, exceeds \( t \). Define the conditional density of \( Y(t) \) by

\[
f^*_t(y) = \frac{\partial}{\partial y} P(Y(t) \leq y | T > t).
\]  

Then it follows from the more general proof outlined in Appendix A that

\[
\frac{\partial f^*_t(y)}{\partial t} = -\frac{\partial}{\partial y} [a(t, y)f^*_t(y)] + \frac{1}{2} \frac{\partial^2}{\partial y^2} [b^2(t, y)f^*_t(y)] \\
- \mu(t, y)f^*_t(y) + \bar{\mu}(t)f^*_t(y),
\]  

where

\[
\bar{\mu}(t) = E[\mu(t, y) | T > t].
\]  

This generalization of the K1-P equation is similar to (5) except for the additional factor given by (8). This factor, which may be interpreted as the expectation of the observed force of mortality at time \( t \), renormalizes \( f^*_t(y) \) to unit mass using the additional information known about survival.
C. The Model when Death and a Variable Are Observed

Now suppose that there is an additional physiological or environmental variable \( X(t) \) that is observed for individuals over time. In particular, suppose that in addition to (1) the following two equations describe the time path of an individual:

\[
\begin{align*}
    dY(t) &= a(t, Y(t), X(t)) \, dt + b(t, Y(t), X(t)) \cdot dW_1(t) \\
    dX(t) &= A(t, Y(t), X(t)) \, dt + B(t, X(t)) \cdot dW_2(t),
\end{align*}
\]

(9) and

(10)

where \( W_1 \) and \( W_2 \) are Wiener processes independent of each other and of the initial values \( X(0) \) and \( Y(0) \). Define the conditional density of \( Y(t) \) by

\[
    f_{\delta}^{**}(y) = \frac{\partial}{\partial y} P(Y(t) \leq y \mid T > t, X_0),
\]

(6')

where \( X_0 \) represents the entire history of the process \( X \) from time 0 to time \( t \). Then as indicated in Appendix A,

\[
    \frac{\partial f_{\delta}^{**}(y)}{\partial t} = - \frac{\partial}{\partial y} \left[ a(t, y, X(t)) f_{\delta}^{**}(y) \right] + \frac{1}{2} \frac{\partial^2}{\partial y^2} \left[ b(t, y, X(t)) f_{\delta}^{**}(y) \right]
    - \mu(t, y, X(t)) f_{\delta}^{**}(y) + \bar{\mu}(t, X_0) f_{\delta}^{**}(y)
    + f_{\delta}^{**}(y) \cdot \frac{A(t, y, X(t)) - \bar{A}(t, X_0)}{B^2(t, X(t))} \cdot (dy - \bar{A}(t, X_0) \, dt),
\]

(11)

where

\[
    \bar{A}(t, X_0) = E(A(t, Y(t), X(t)) \mid T > t, X_0),
\]

(12)

Note the similarity of (11) to (5) and (7). The additional, final term in (11) describes the effect of observing \( X(t) \).

D. Further Extensions of the Model

The processes considered up until now have been Markovian processes: the coefficients in the stochastic differential equations (2), (9), and (10) depend only on the current values of the variables. That is, it is assumed that the current values on the individual’s physiological variables are reasonable approximations of the individual’s physiological “state” and, consequently, will determine the future changes of that state except for stochastic effects. When \( X(t) \) is observed, it is possible to generalize the process to depend on the entire time path \( X_0 \). This implies that the prior physiological charac-
characteristics of the individual, and possibly the trajectory of change of those physiological characteristics, can be included in the definition of physiological state. For example, having elevated blood pressure at the current time may not be sufficient to describe the state of the individual with respect to mortality risks. Risk may be more dependent upon accumulated damage (perhaps represented by the elevation of pressure over a long period of time) or upon extreme values (e.g., the number of times a blood pressure threshold was exceeded). Such processes may be modeled by replacing $X(t)$ in (9), (10), (11), and (12) by $X^i(t)$. A sketch of the proof is given in Appendix A.

Each of the three formulations presented above can be readily extended to the general case of any number of state variables. This extension requires the substitution of the appropriate matrices.

III. Estimating the Unobserved Variable

Woodbury and Manton (1977) suggest some assumptions and restrictions for estimating the parameters of the observed process. Some of these will be useful for estimating characteristics of the unobserved variables. In the following we apply their general time series approach to the various formulations described above.

A. The Basic Model

Consider the first formulation of the model, presented above in Section II.A, in which neither an individual's time of death nor an individual's values on the state variable are observed. Assume that the distribution of individuals on this variable follows a Gaussian distribution at time 0. Furthermore, restrict the stochastic equation in (2) as follows:

$$dY(t) = a_0(t) + a_1(t) Y(t) dt + b(t) dW_1(t).$$  \hspace{1cm} (13)

It is obvious that the distribution of $Y(t)$ is Gaussian at any time $t$. The mean, $m(t)$, and variance, $\gamma(t)$, of this distribution are given by

$$\frac{dm(t)}{dt} = a_0(t) + a_1(t) m(t)$$  \hspace{1cm} (14)

and

$$\frac{d\gamma(t)}{dt} = 2a_1(t) \gamma(t) + b^2(t).$$  \hspace{1cm} (15)
B. The Model when Only Death Is Observed

Now consider the second formulation presented above. Assume that $Y(t)$ has a Gaussian distribution at time 0 and that the force of mortality is a quadratic function of this variable:

$$\mu(t, Y(t)) = \mu_0(t) + Y(t) \mu_1(t) + Y^2(t) \mu_2(t).$$

(16)

Furthermore, restrict the stochastic differential equation in (2) as follows:

$$dY(t) = a_0(t) + a_1(t) Y(t) dt + b(t) dW_1(t).$$

(17)

It follows that the distribution of $Y(t)$ conditional on $I(t) = 1$ or $T > t$ (in other words, among the surviving population) is Gaussian at any time $t$: proof of this is a special case of the more general proof sketched in Appendix A; a specific proof may be found in Yashin (1983). The mean $m(t)$ and variance $\gamma(t)$ of this distribution are given by

$$\frac{dm(t)}{dt} = a_0(t) + a_1(t) m(t) - \gamma(t) \mu_1(t) - 2m(t) \gamma(t) \mu_2(t)$$

(18)

and

$$\frac{d\gamma(t)}{dt} = 2a_1(t) \gamma(t) - 2\mu_2(t) \gamma^2(t) + b^2(t).$$

(19)

Note the additional terms in (18) and (19) compared with (14) and (15). The observed force of mortality is given by the following formula:

$$\bar{\mu}(t) = \mu_0(t) + m(t) \mu_1(t) + (m^2(t) + \gamma(t)) \mu_2(t).$$

(20)

If restrictions are placed on the $\mu$'s in this formula—e.g., so that they are constant or follow certain specified functional forms—then it may be possible to estimate their values given the observed values of $\bar{\mu}$. Another approach is to restrict (16) to

$$\mu(t, Y(t)) = Y^2(t) \cdot \mu(t).$$

(21)

This constraint is analogous to the formulation in Vaupel et al. (1979); $Y^2$ corresponds to the variable called "frailty." The formula in (20) reduces to

$$\bar{\mu}(t) = (m^2(t) + \gamma(t)) \cdot \mu(t),$$

(22)

so that the time path of $\mu(t)$ can be calculated from the observations of $\bar{\mu}(t)$ and the estimates of $m(t)$ and $\gamma(t)$. 
C. The Model When Death and $X(t)$ are Observed

Suppose now that $X(t)$ is observed. Assume that the distribution of the variable $Y(0)$ where individual values are unobserved, conditional on the observed $X(0)$, is Gaussian and that the force of mortality is a quadratic function of $Y(t)$:

$$\mu(t, Y(t), X'_0) = \mu_0(t, X'_0) + Y(t) \mu_1(t, X'_0) + Y^2(t) \mu_2(t, X'_0).$$  \hspace{1cm} (23)

In addition, restrict the stochastic differential equations as follows:

$$dY(t) = \left[ a_0(t, X'_0) + a_1(t, X'_0) Y(t) \right] dt + b_1(t, X'_0) dW_1(t)$$
$$+ b_2(t, X'_0) dW_2(t)$$  \hspace{1cm} (24)

and

$$dX(t) = \left[ A_0(t, X'_0) + A_1(t, X'_0) Y(t) \right] dt + B(t, X'_0) dW_2(t).$$  \hspace{1cm} (25)

Note that (24) and (25) are more general than (9) and (10). First, the coefficients may depend on the entire history of $X'_0$: this represents the extension to the non-Markovian case. Second, the first equation now depends on both Wiener processes (i.e., $W_1$ and $W_2$). This is a straightforward generalization that may be useful in estimation.

As outlined in Appendix B, it follows that the distribution of $Y(t)$ conditional on $X(t)$ and $T > t$ is Gaussian. Furthermore, the mean and variance of this conditional distribution are given by

$$dm(t) = \left[ a_0(t, X'_0) + a_1(t, X'_0) m(t) - \gamma(t) \mu_1(t, X'_0) - \gamma(t) \right]$$
$$\times \mu_2(t, X'_0) \right] dt$$
$$+ \left[ b_2(t, X'_0) B(t, X'_0) + A_1(t, X'_0) \gamma(t) \right]$$
$$\times \left[ dX(t) - (A_0(t, X'_0) + A_1(t, X'_0) m(t)) dt \right].$$  \hspace{1cm} (26)

and

$$\frac{dy(t)}{dt} = 2 \left[ a_1(t, X'_0) - \frac{b_2(t, X'_0)}{B(t, X'_0)} A_1(t, X'_0) - \mu_2(t, X'_0) \gamma(t) \right]$$
$$\times \gamma(t) + b_1^2(t, X'_0) - \frac{A_1^2(t, X'_0)}{B^2(t, X'_0)} \gamma(t).$$  \hspace{1cm} (27)

These two equations are similar to the previous expressions for the mean and variance in (18) and (19) except for the final terms (and terms arising from the inclusion of $W_2$ in (24)). These final terms can be viewed as corrections
introduced because information is available about $X'_0$. The terms will look familiar to students of continuous-time Kalman filters. Indeed, one way of interpreting (26) and (27) is that they generalize the usual Kalman filter equations to include the force of mortality.

The observed force of mortality can be related to the observed variables and the distribution of the unobservable variables by

$$\bar{\mu}(t, X'_0) = \mu(t, X'_0) + m(t) \mu_1(t, X'_0) + (m^2(t) + \gamma(t)) \mu_2(t, X'_0). \quad (28)$$

D. Discrete Time Observations

In most empirical studies, individual values on variables are not monitored continuously but are observed from time to time. This section describes how the formulas developed above may be applied to the case of discrete time observations. Assume that the unobserved process is governed by the stochastic differential equation

$$dY(t) = (a(t, X) + a_1(t, X) Y(t)) dt + b(t, X) dW_t, \quad (29)$$

where the process $X$ is now the sequence of $(t_n, X_n)$, $n > 0$. That is, there is a sequence of observation times $t_1, t_2, \ldots, t_n$ and a sequence of measurements $X_1, X_2, \ldots, X_n$. The $X_n$ sequence can be described by the generating procedure

$$X_n = A(T_n, X) Y(T_n) + D(T_n, X) \bar{\xi}_n, \quad (30)$$

where $A(t, X)$ and $D(t, X)$ (as well as $a(t, X), a_1(t, X), b(t, X)$) are known functions of $t$ and the entire history of the process $X$ up to but not including time $t$ and where $\bar{\xi}_n$ is a sequence of Gaussian-distributed random variables with mean 0 and variance 1. As before, we assume that the force of mortality may be represented by

$$\mu(t, X, Y(t)) = \mu_0(t, X) + Y(t) \mu_1(t, X) + Y^2(t) \mu_2(t, X), \quad (31)$$

where the $\mu_0$ and $\mu_2$ are nonnegative, measurable functions of $t$ and the entire history of $X$ up to but not including time $t$.

By generalizing the method of proof used in Yashin (1980) it can be shown that the conditional distribution of $Y(t)$ given $I(t) = 1$ (i.e., $T > t$) and $X$ is Gaussian. The mean and variance of this distribution are

$$m(t) = m(0) + \int_0^t \left[ a_0(s, X) + a_1(s, X) m(s) - \gamma(s) \mu_1(s, X) \right] ds + \sum_{t_n < t} A(t_n, X) \gamma(t_n) (A^2(t_n, X) \gamma(t_n))^{-1} \cdot (X_n - A(t_n, X) m(t_n)), \quad (32)$$
and

\[
\gamma(t) = \gamma(0) + \int_0^t \left[ \sum_{i=1}^n \frac{1}{2} \left( a_i(s, X) \gamma(s) + b_i(s, X) - 2\mu_i(s, X) \gamma(s) \right)^2 + \sum_{i=1}^n \frac{1}{2} \gamma^2(0) \right] ds
\]

These equations may be viewed as generalizations of both continuous time and discrete time Kalman filter algorithms.

IV. Applications

A. General Observations

To use the model empirically, it is necessary to produce estimates of the values of the coefficients in the stochastic differential equations (25) and either (24) or (29). Although discussion of the details of statistical estimation is beyond the scope of this paper, we note that if observations are available on a population of individuals across time and over age, then the coefficients of these equations are estimable given the appropriate identifying constraints. Alternatively, previous theoretical and empirical research may suggest values or functional forms for the coefficients that will facilitate estimation. In particular, there have been a number of longitudinal studies of aging processes (e.g., the first and second Duke longitudinal studies of normative aging) which can provide estimates of the age rate of decline of a broad range of physiological parameters. These estimates could be employed directly in the equations.

Given the coefficients, (26) and (27) or (32) and (33) permit estimation of the mean and variance of the conditional distribution of the unobservable variable. Equation (28) can then be used as the basis for estimating the force of mortality for an individual with any specified characteristics and at any age. As noted earlier, this estimation might require specifying certain functional forms for \( \mu_0 \), \( \mu_1 \), and \( \mu_2 \). Alternatively, it might be assumed that \( \mu_0 \) and \( \mu_1 \) are equal to zero, in which case the values of \( \mu_2 \) over time can be immediately calculated from the observations of \( \bar{\theta} \) over time.

B. Unobserved Risk Factors

The model may be useful in a variety of applications where data are available over time concerning some variables, but there is reason to believe that other significant variables are unobserved. In some cases enough theoretical or empirical knowledge may be available about these unobserved variables so that the initial probability distributions and stochastic
differential equations can be specified with some confidence. In such cases estimation of the evolution of the unobserved variables may be of considerable interest. In other cases, it may be suspected that some unmeasured factor such as "frailty" is an important source of heterogeneity in the population. Such a variable may have to be introduced by imposing constraints in the model. For instance, Vaupel et al. (1979) assume that an individual's frailty is constant over age and that the distribution of frailty among individuals follows a specific distributional form. In some studies the unobserved variable may not be of direct interest: it may be viewed as a nuisance parameter important only because it obscures the actual relationships among the variables of particular interest.

For example, consider a longitudinal analysis of chronic illness based on the kind of information collected, say, in the Framingham study. Manton et al. (1979) and Woodbury et al. (1979, 1981) present analyses of this sort, based on the insights of the Woodbury-Manton model. In their analyses, the change in coronary heart disease risk factors in the study population was modeled as an autoregressive process adjusted for the effects of systematic mortality selection. It seems likely the population was subject to risk factors not fully represented by the available measurements of systolic and diastolic blood pressure, serum cholesterol, uric acid, etc. The stochastic differential equations presented here and the Kalman filter equations generalized to represent the effects of mortality selection offer a range of strategies for (a) estimating the impact of unobserved risk factors, and (b) identifying the "true" effects of observed risk variables.

C. Partially Overlapping Studies

Sometimes longitudinal data are available from several related studies such that, though some variables may be observed in all studies, other variables are observed in only some studies. Having a set of such studies can greatly facilitate the estimation of the model parameters. For instance, the Woodbury-Manton model has served as the basis for analyses of coronary heart disease risks not only in the Framingham study population, but also in the populations observed in the Duke Longitudinal Study of Aging (Manton and Woodbury, 1983), and in an unpublished Kaunas, Lithuania, study. Partially overlapping sets of observed variables were available for these three analyses. The Duke study differed from the Framingham study in that uric acid serum concentrations were not observed, but scores were taken on the Wechsler Adult Intelligence Scale. In the Kaunas data set, intelligence test data were not available, but certain other laboratory measurements were made.

To compare and synthesize such imperfectly coordinated data sets, it may be useful to employ a model that includes all of the variables observed in any of the studies. The model could then be applied to the different studies
by specifying which variables were observed and which were not observed. The effects of all of the variables across all of the studies could then be compared. Furthermore, process parameters estimated for an "observable" in one study could be applied to another study where that variable was "unobserved."

D. Measurement Errors and Indirect Measurements

Most variables can only measured with some error: sometimes the noise can be severe. In other cases, a variable of prime interest cannot be observed directly, but a correlated variable can be monitored and used as an index. For instance, the elasticity of blood vessels may be important in coronary heart disease processes, but observations may only be available on blood pressure. Indeed, most of the measurements available in studies of aging processes may only indirectly reflect the underlying physiological state variables.

As noted above, the formulas presented for estimating the mean and variance of the unobserved variables can be interpreted as extensions of the Kalman filter equations developed to detect signals in noisy measurements. Thus, the Kalman filter type equations presented here can be useful in identifying the true variables of the process, in the face of measurement error or indirect assessment, from studies with multiple measurements taken over time.

E. Assumptions

Efforts to apply the model will, of course, be dependent on the reasonableness of model assumptions for a specific application. In this section, we discuss assumptions and some strategies for extending the model's applicability to certain situations.

1. Gaussian distribution. The distribution of the unobserved variables conditional on the observed variables at time zero is assumed to be Gaussian. Furthermore, the model implies that this conditional distribution among survivors will be Gaussian at any time t. For some variables this may not be true, but a transform of a variable may be more or less Gaussian distributed. For example, Manton and Woodbury (1979) use the logarithms of pulse pressure, diastolic blood pressure, and serum cholesterol level. Consideration of the reasonableness of this assumption must be based on available theoretical insight about the dynamics of the unobserved variable (see Manton and Stallard, 1981).

2. Quadratic hazard. The force of mortality is assumed to be a quadratic function of the unobserved variables. This assumption is closely tied to the Gaussian assumption, as the following example illustrates. Let
\(\mu(t, Y)\) be the force of mortality at time \(t\) for an individual with unobserved characteristic \(Y\). Suppose

\[
\mu(t, Y) = Y^2 \mu(t),
\]

(34)

where \(\mu(t)\) might be interpreted as the force of mortality for some standard individual for whom \(Y\) equals one. Now consider an alternative formulation:

\[
\mu(t, z) = z \mu(t),
\]

(35)

where \(z\) is a characteristic that equals \(Y^2\). This formulation is the one used in the "frailty" model proposed by Vaupel et al. (1979) and applied in studies by Manton et al. (1981) and Horiuchi and Coale (1983). Finally, consider the formulation where

\[
\mu(t, x) = \mu(t) e^x,
\]

(36)

where \(x\) is a characteristic that equals the logarithm of \(Y^2\). This approach has been adopted in a variety of studies, including Heckman and Singer (1982). Given the appropriate probability distributions, all three formulations can be made equivalent. For instance, the first formulation with \(Y\) following a Gaussian distribution with mean zero and variance one is equivalent to the second formulation with \(z\) following a Gamma distribution with scale parameter one and shape parameter 0.5.

In some respects the second formulation, involving \(z\), is the most transparent since \(z\) can be interpreted as measuring the relative risk of mortality for an individual compared to some "standard" individual. Since \(Y\) does not have to be a single variable, but can be a vector of variables, it is possible to consider \(z\) defined by

\[
z = Y^T a Y,
\]

(37)

where \(a\) is a matrix. In this case, \(z\) will have a distribution known as a quadratic form of the Gaussian distribution. Such quadratic forms are very flexible and can take on a variety of shapes. Thus, the assumption that each variable in the unobserved set of variables \(Y\) is Gaussian distributed can be readily generalized to the case where the unobserved variables can, in effect, follow a quadratic form of the Gaussian distribution. Biologically the quadratic form of the hazard is reasonable for physiological parameters subject to homeostatic forces: variables that are essential to physiological functioning should have a viable interior range and nonviable exterior ranges where homeostasis is thought to break down.

3. Differential processes. Both the observed and unobserved variables in our model are assumed to be continuous and governed by a differential
process. In a variety of studies this may be satisfactory. In some instances, however, categorical variables that are either constant over time or that follow some jumping process may be important. Constant categorical variables, like sex, race, or national origin, can be handled by stratifying the data. Discrete-state variables that jump from one state to another pose a much more difficult problem. Examples of such variables that may be relevant to studies of aging and mortality include marital status, type of employment, place of residence, and such factors as whether an individual is hospitalized or in a nursing home, has had a stroke or a heart attack, has quit smoking, and so on. It is possible to extend the models presented here to the more general case where some of the observed or unobserved variables follow a jumping process as opposed to a differential process.

V. Discussion

In both empirical and theoretical studies of human aging and mortality, the need for modeling individual differences in aging processes has been repeatedly demonstrated (e.g., Strehler, 1977; Economos, 1982; Manton and Woodbury, 1983). Unfortunately, there are many instances where those differences are due to unobserved variables. Indeed, the nature of the sources of these differences, such as differences in the age-related loss of functional "vitality" or the impact on longevity of genetic factors, suggest that difficulties in measurement and conceptualization will dictate that such individual properties will remain at least partially hidden for a long time. Nonetheless, successfully coping with the effects on aging processes of such latent heterogeneity will be a necessary component of adequate models of human aging and mortality. For example, Economos (1982) has argued for the necessity of joining "Simm's idea of statistically distributed individual aging rates" with Gompertz's concept of "accelerated decline of vitality" in order to relate the observed pattern of rates of aging with the observed pattern of the rates of dying. Indeed, the logic by which these concepts are related is that of a diffusion process where temporary sojourns above a threshold value cause the rate of increase in mortality rates to be more rapid than the rate of decline of physiological vitality.

The model we have presented provides a flexible strategy for assessing the impact of such heterogeneity on human aging and mortality processes. In particular, it generalizes the notion of the effects of heterogeneity from that of a fixed distribution to the effects of an unobserved process. Thus, it can lead to an empirical strategy for assessing both functional change and mortality which is rich enough to represent the complexity of current conceptual models of human aging and mortality.

We presented our model as a development of the Woodbury–Manton
model of aging and mortality published by this journal. Our model can also be viewed as having roots in analyses of failure processes done by numerous researchers in a variety of disciplines. Often analysts working in the various fields of statistics (e.g., Lundberg, 1940), labor economics (e.g., Blumen, Kogen, and McCarthy, 1955), sociology (e.g., Singer and Spilerman, 1974), reliability engineering (e.g., Harris and Singpurwalla, 1968), demography (e.g., Sheps and Menken, 1973), and health policy analysis (e.g., Shepard and Zeckhauser, 1977), were only partially aware of the mutual relevance of their methodological research.

The thrust of much of this diverse body of research is how to cope with the effects of population heterogeneity on the parameters of the process of interest. The most common conceptualization of the problem is that there is some unobserved variable that influences the likelihood that an individual will “die” at some particular time. Sometimes this variable is of direct interest; in other cases, it is essentially a nuisance. When it is of direct interest, methods to estimate parameters of its distribution may be important. But whether it is of interest or just a nuisance, one must be concerned with its effects in order to uncover the underlying relationship between the force of “mortality” and the variables of interest. In nearly all the previous work on heterogeneity, the value of the unobserved variable is assumed to be constant over time for each individual. The more general approach developed in this paper may thus be useful in a variety of applications where unobserved variables change over time.

APPENDIX

A. Proof of the Generalized Kolmogorov–Fokker–Planck Equation

Consider the random process \((Y \times X)\) defined on probability space \((\Omega, H, P)\) by the relations

\[
dY(t) = a(t, Y(t), X'_0) \, dt + b(t, Y(t), X'_0) \, dW_1(t)
\]

and

\[
dX(t) = A(t, Y(t), X'_0) \, dt + B(t, X'_0) \, dW_2(t),
\]

where \(W_1(t)\) and \(W_2(t)\) are independent Wiener processes that are also independent of the initial conditions \(Y(0)\) and \(X(0)\). Coefficients \(a, A,\) and \(b\) are measurable functions of \(t, Y(t),\) and the entire history of the process \(X\) from time 0 to time \(t\). \(B\) is a positive, measurable function of \(t\) and the entire history of the process \(X\). \(I(t)\) is a two-state \((1, 0)\) continuous time process with \(I(0) = 1\), with the transition intensity function \(\mu(t, Y(t), X'_0)\), which is a
measurable function of \( t, Y(t) \), and the entire history of the process \( X \) up to time \( t \).

The proof of the generalized Kolmogorov–Fokker–Planck equation for the density of the unobserved variable conditional on \( I(t) = 1 \) and \( X'_0 \) is based on the formula for the conditional mathematical expectation of an arbitrary, bounded, doubly differentiable function \( F(Y(t)) \). This formula may be derived as a consequence of the general estimation approach based on semimartingale theory (Jacod, 1979; Bremaud, 1980), as well as the methods of filtration of random processes with jumping components (Yashin, 1969) and the analogous methods given in Liptser and Shirjaev (1977). Here we sketch the proof.

Using Bayes’ formula, one can write

\[
E(F(Y(t)) \mid I(t) = 1, X'_0) = E'(F(Y(t)) \cdot \Psi(t)), \quad (A3)
\]

where \( \Psi(t) \) is the likelihood ratio given by

\[
\Psi(t) = \exp \left\{ \int_0^t \frac{A(u, Y(u), X'_0) - \bar{A}(u, X'_0)}{B(u, X'_0)} \, d\bar{W}(u) \\
- \frac{1}{2} \int_0^t \frac{(A(u, Y(u), X'_0) - \bar{A}(u, X'_0))^2}{B^2(u, X'_0)} \, du \\
+ \int_0^t (\bar{\mu}(u, X'_0) - \mu(u, Y(u), X'_0)) \, du \right\}, \quad (A4)
\]

where

\[
\bar{W}(t) = \int_0^t \frac{dX(u) - \bar{A}(u, X'_0) \, du}{B(u, X'_0)} \quad (A5)
\]

is the Wiener process with respect to the family of \( \sigma \)-algebras generated by the process \( X \), and where

\[
\bar{A}(t, X) = E(A(t, Y(t), X'_0) \mid I(t) = 1, X'_0) \quad (A6)
\]

and

\[
\bar{\mu}(t, X) = E(\mu(t, Y(t), X'_0) \mid I(t) = 1, X'_0). \quad (A7)
\]

The symbol \( E' \) means the operation of mathematical expectation with respect to the marginal probability measure concentrated on the component \( \overline{W}_1 \) of the Wiener process.
Using Ito’s differential rule (Liptser and Shirjaev, 1977), one can readily transform (A4) into the differential relationship

\[
d\Psi(t) = \Psi(t) \left[ \frac{A(t, Y(t), X_0^t) - \bar{A}(t, X_0^t)}{B(t, X_0^t)} d\tilde{W}(t) - (\mu(t, Y(t), X_0^t) - \bar{\mu}(t, X_0^t)) dt \right]. \tag{A8}
\]

In order to calculate (A3), represent the product of \( F(Y(t)) \) and \( \Psi(t) \) by using Ito’s differential rule. This yields

\[
F(Y(t)) \Psi(t) = F(Y(0)) \Psi(0) + \int_0^t F'(Y(u)) \Psi(u) a(u, Y(u), X_0^u) du
\]

\[
+ \int_0^t F(Y(u)) \Psi(u) \left[ \frac{A(u, Y(u), X_0^u) - \bar{A}(u, X_0^u)}{B(u, X_0^u)} d\tilde{W}(u) - (\mu(u, Y(u), X_0^u) - \bar{\mu}(u, X_0^u)) du \right]
\]

\[
+ \int_0^t F'(Y(u)) \Psi(u) b(u, Y(u), X_0^u) dW(u)
\]

\[
- \frac{1}{2} \int_0^t F''(Y(u)) \Psi(u) b^2(u, Y(u), X_0^u) du, \tag{A9}
\]

where \( F' \) and \( F'' \) are the first and second order derivatives of \( F \) with respect to \( Y \).

Taking the mathematical expectation \( E' \) of both sides of (A9), we get

\[
E(F(Y(t)) \mid I(t) = 1, X_0^t)
\]

\[
= E(F(Y(0)) \mid I(0) = 1, X_0) + \int_0^t E'(F'(Y(u)) a(u, Y(u), X_0^u) \Psi(u)) du
\]

\[
- \frac{1}{2} \int_0^t E'(F''(Y(u)) b^2(u, Y(u), X_0^u) \Psi(u)) du
\]

\[
- \int_0^t E'(F(Y(u)) \mu(u, Y(u), X_0^u) \Psi(u)) du
\]

\[
+ \int_0^t E'(F(Y(u)) \bar{\mu}(u, X_0^u) \Psi(u)) du
\]

\[
+ \int_0^t E' \left( F(Y(u)) \Psi(u) \cdot \frac{A(u, Y(u), X_0^u) - \bar{A}(u, X_0^u)}{B(u, X_0^u)} \right) d\tilde{W}(u). \tag{A10}
\]
By again using Bayes’ formula one can show
\[ E(F(Y(t)) \mid I(t) = 1, X_0^t) \]
\[ = E(F(Y(0)) \mid I(0) = 1, X_0) \]
\[ + \int_0^t E(F'(Y(u)) \cdot a(u, Y(u), X_u^u) \mid I(u) = 1, X_0^u) \, du \]
\[ - \frac{1}{2} \int_0^t E(F''(Y(u)) b^2(u, Y(u), X_0^u) \mid I(u) = 1, X_0^u) \, du \]
\[ - \frac{1}{2} \int_0^t E(F''(Y(u)) A(u, Y(u), X_0^u) \mid I(u) = 1, X_0^u) \, du \]
\[ + \int_0^t E \left( F(Y(u)) \left\{ \frac{A(u, Y(u), X_0^u) - \tilde{A}(u, X_0^u)}{B(u, X_0^u)} \right\} \mid I(u) = 1, X_0^u \right) \, d\tilde{W}(u). \]

Using the arbitrary doubly differentiable function \( F(Y) \) such that
\[ F(\pm \sim) = F'(\pm \sim) = F''(\pm \sim) = 0 \]
and rewriting (A11) in terms of the integral with respect to the conditional density
\[ L^*_t(y) = \frac{\partial}{\partial y} P(Y(t) \leq y \mid I(t) = 1, X_0^t) \]
one can finally get the conditional Kolmogorov-Fokker-Planck equation given in the main text.

B. Proof that the Conditional Distribution is Gaussian

In order to prove that the conditional density \( f_t(y) \) is Gaussian, some additional assumptions are needed. We assume that the coefficients \( a, A, \) and \( \mu \) have the following forms:
\[ a(u, Y(u), X_0^u) = a_0(u, X_0^u) + a_1(u, X_0^u) Y(u) \]
\[ A(u, Y(u), X_0^u) = A_0(u, X_0^u) + A_1(u, X_0^u) Y(u) \]
\[ \mu(u, Y(u), X_0^u) = \mu_0(u, X_0^u) + \mu_1(u, X_0^u) Y(u) + \mu_2(u, X_0^u) Y^2(u), \]
which are functions of time and of the entire past of the process \( X \) from time 0 up to time \( t \). We assume also the initial condition that \( Y(0) \) is Gaussian distributed, conditional on \( I(0) = 1 \) and \( X_0^t \), and that \( F(Y(t)) \) has the special form
\[ F(Y(t)) = e^{i\alpha Y(t)}. \]
Define $\Psi_t$ by

$$\Psi_t = E(e^{iaY(t)} | I(t) = 1, X_0^t). \quad (B3)$$

For this special case (A11) may be written as

$$\Psi_t = \Psi_0 + ia \int_0^t a_0(u, Y(u)) \Psi_u du + \alpha \int_0^t a_1(u, X_0^u) \Psi_u du$$

$$- \frac{\alpha^2}{2} \int_0^t \Psi_u b_2(u, X_0^u) du + \int_0^t \mu_2(u, X_0^u) \Psi_u du$$

$$+ \int_0^t \mu_1(u, X_0^u) \bar{Y}_2(u) \Psi_u + \int_0^t \mu_1(u, X_0^u) m(u) \Psi_u du$$

$$- i \int_0^t \mu_1(u, X_0^u) \Psi_u' du$$

$$- i \int_0^t \Psi_u' \frac{A(u, X_0^u)}{B(u, X_0^u)} d\bar{W}(u) - \int_0^t \Psi_u \frac{A(u, X_0^u)m(u)}{B(u, X_0^u)} d\bar{W}(u), \quad (B4)$$

where $\Psi'$ and $\Psi''$ denote the first and second derivatives of $\Psi$ with respect to $a$ and $m(t) = E(Y(t) | I(t) = 1, X_0^t)$. Then the function $\Psi_0$ can be written as

$$m(t) = E(Y(t) | I(t) = 1, X_0^t). \quad (B5)$$

Denote by $m_0$ and $\gamma_0$ the mean and variance of the conditional distribution of $Y_0$. Then the function $\Psi_0$ can be written as

$$\Psi_0 = exp\{iam_0 - \frac{1}{2} \alpha^2 \gamma_0\}. \quad (B6)$$

Given this particular form and the equation for $\Psi_t$, we seek $\Psi_t$ in the similar form

$$\Psi_t = exp\{iam(t) - \frac{1}{2} \alpha^2 \gamma(t)\}, \quad (B7)$$

where $m_t$ and $\gamma_t$ satisfy the following stochastic differential equations

$$dm(t) = c_1(t) dt + d_1(t) d\bar{W}(t)$$

$$d\gamma(t) = c_2(t) dt + d_2(t) d\bar{W}(t). \quad (B8)$$

The coefficients in (B8) can be found from (B1) and (B7). Using the equalities

$$\Psi'_m = ia \Psi \Psi''_m = -\alpha^2 \Psi, \quad \Psi''_m = -\frac{1}{4} ia^3 \Psi$$

$$\Psi'_\gamma = -\frac{1}{2} \Psi \alpha^2, \quad \Psi''_\gamma = -\frac{1}{4} \Psi \alpha^4 \quad (B9)$$
and comparing the stochastic differential of $\Psi_t$ represented in terms of $m(t)$ and $\gamma(t)$ with the right-hand side of (B4), we have

\[ c_1(t) = a_0(t, X) + a_1(t, X) m(t) - \gamma(t)(\mu_1(t, X) + \mu_2(t, X) m(t)) \]

\[ d_1(t) = \frac{A(t, X)}{B(t, X)} \gamma(t), \quad d_2(t) = 0 \]  

(B10)

\[ c_2(t) = b^2(t, X) - 2a_1(t, X) \gamma(t) - \mu(t, X) \gamma^2(t) - \frac{A(t, X)}{B(t, X)} \gamma^2(t). \]

It remains to be shown that the equation for $\gamma_t$ has a unique solution. Proof of this follows easily from the approach suggested by Liptser and Shirjaev (1977). Furthermore, generalization to the case described in Section III.C—i.e., when noise in $X$ and $Y$ is correlated—also follows easily from Liptser and Shirjaev.
